Revision of the *Iridomyrmex discors* Species-group (Hymenoptera: Formicidae)

S. O. SHATTUCK
CSIRO Division of Entomology, G.P.O. Box 1700, Canberra, A.C.T. 2601.

**ABSTRACT** The *discors* species-group of the ant genus *Iridomyrmex* Mayr is defined for the first time and revised at the species level. The group is composed of two species, *I. discors* Forel and *I. obscurior* Forel (the latter previously a subspecies of *I. discors*). The names *I. discors aeneogaster* Wheeler, *I. discors occipitalis* Forel and *I. discors occipitalis exilior* Forel (an unavailable infrasubspecific name) are newly synonymised with *I. discors*. *I. discors* is distributed broadly across southern Australia (excluding Tasmania) and occupies a wide range of habitats. *I. obscurior* is known from only two collections, both relatively moist sites in southeastern Australia.

**Introduction**
Members of the ant genus *Iridomyrmex* Mayr are common and prominent members of many Australian ecosystems (Andersen and Patel 1994; Greenslade and Halliday 1982). They are frequently encountered during ecological studies and are well represented in most entomological collections. Unfortunately, limited attention has been given to the species-level taxonomy of the genus and identifications are difficult. In the present study the *I. discors* species-group is defined and revised at the species level. The group contains five specific or subspecific names (one an unavailable infrasubspecific name). During the current study the group was found to contain two valid species, *I. discors* Forel and *I. obscurior* Forel. The remaining three names represent junior synonyms of *I. discors*. Although *I. discors* is relatively common it has received little discussion in the literature. The only detailed study is that of Cox et al. (1989), who examined its chemical constituents.

**Taxonomic status of Iridomyrmex and diagnosis of the Iridomyrmex discors group**
For the current status and identification of *Iridomyrmex* see Shattuck (1992a, b). Members of the *I. discors* group can be separated from other species in the genus by the presence of a relatively broad head (Fig. 1), short antennal scapes (Fig. 2), and erect or suberect hairs on the antennal scapes and tibiae. This group is morphologically most similar to smaller members of the *I. purpureus* group and to species related to *I. mayri* Forel. They may be separated from both of these by the head shape and scape length relative to head width, and from *I. mayri* and relatives by the larger number of erect hairs on the antennal scapes and the shorter anteromedial clypeal projection (Figs 3, 4), which projects at most 0.02 mm

Fig. 1. Distribution of head length and width measurements (in millimetres) for *I. discors*, *I. obscurior*, *I. mayri* group and *I. purpureus* group.
anterior of the anterolateral prominences in the
I. discors group and between 0.04 mm and 0.09
mm anterior in I. mayri and relatives.

Methods and abbreviations

Size and shape characters were quantified and are
reported as lengths or indices. Measurements were
made with a stereo microscope using a dual-axis
stage micrometer wired to digital readouts. All
measurements were recorded in thousandths of
millimetres, but are expressed here to the nearest
hundredth. All head measurements (EL, EW, HL,
HW; see below for abbreviations) were taken in
full-face (dorsal) view without moving the head
between measurements. Longitudinal mesosomal
length measurements (PnL, ML, PpL) were taken
in lateral view, parallel to a line ("measuring
axis") drawn between the anterior-most point of
the pronotal collar and the posterior-most point
of the propodeal process dorsal of the petiolar
insertion.

Figures showing the following measurements
can be found in Shattuck (1993): EL, EW, HL,
HW, ML, PnL, PpL and SL.

Abbreviations used are: Characters: CI,
cephalic index: HW/HL; EL, maximum eye
length measured in full face view; EW, maximum
eye width measured in full face view; HL,
maximum head length in full face view; PnL,
pronotal length measured from the anterior-most point
of the pronotal collar and the posterior-most point
of the propodeal process dorsal of the petiolar
insertion.

Key to species of Iridomyrmex discors group
(workers)

1. Head broad (CI usually greater than 0.95,
ocasionally lower) (Fig. 1); scapes short (SI
less than or equal to 0.99) (Fig. 2); propodeal
dorsum rounded in lateral profile (Figs 5-7)

I. discors Forel

Head narrow (CI less than 0.94) (Fig. 1);
scapes long (SI greater than or equal to 1.00)
(Fig. 2); propodeal dorsum flatter in lateral
profile (Fig. 9). . . . . . . . . . . . . . . . . . . . . . . . . . . . I. obscurior Forel
Iridomyrmex discors Forel
(Figs 1, 2, 4–7, 10)

Iridomyrmex discors occipitalis exilior Forel, 1907: 294 (in subspecific name).

**Types.** *I. discors: Queensland*: 8 worker syntypes from Charters Towers (1 in NHMB, see Baroni Urbani 1977; 1 in MCZC; 1 in ANIC; 5 in MHNG).

*I. discors occipitalis: Western Australia*: 5 worker syntypes from Northampton (1 in MCZC; 1 in ANIC; 2 in MHNG; 1 in WAMP).

*I. discors occipitalis exilior: Western Australia*: unspecified material from Northampton (Forel 1907); 3 workers from south-west Australia (specific locality not given) (2 in NHMB, see Baroni Urbani 1977; 1 in OXUM); 17 workers and 7 queens from Subiaco (3 workers in MCZC; 2 workers in ANIC; 1 worker and 1 queen (missing petiole and gaster) in WAMP; 11 workers and 5 queens in MHNG; 1 queen in MVMA) (although unavailable names do not have type material, the above material was examined by Forel (1907) when describing this taxon).

*I. discors aerogaster: South Australia*: holotype worker from Flat Rock Hole, Musgrave Ranges (SAMAA).

**Other material examined** (in ANIC). A.C.T.: Black Mountain (C.M.); Canberra (TG); Capital Hill, Canberra (BBL); New South Wales: 130 km W of Cobar (PJMG); 1 mi (= 1.6 km) N of Mt. Woolakalka (TG); Botany Bay breakwater, Sydney (J. Brophy); Broken Hill (BBL); Broken Hill airport, 31'59'S 141'28'E (SOS); Caldis Dune, Kurnell Peninsula, Sydney (G. **Worker diagnosis.** Head broad (CI usually greater than 0.95, occasionally lower) (Fig. 1); scapes short (SI less than or equal to 0.99) (Fig. 2); propodeal dorsum rounded in lateral profile (Fig. 5-7).

**Worker description.** Pigment colour of head and mesosoma varying from light to dark yellowish-red, with the mandibles slightly darker, and with the head and mesonotum usually similar in colour and slightly darker than the pronotum; petiole and gaster reddish brown; coxae and legs varying from light to dark yellowish-red, with the petiole usually darker than the gaster.
only slightly darker than the mesonotum to distinctly infuscated dark brown. Iridescence present or absent from gaster, when present green or purple. Head pilosity always present and setae numerous on occipital margin, varying from abundant to nearly absent laterally. Dorsal surfaces of mesosoma, petiole and gaster with numerous elongate erect or suberect setae; erect hairs present on all leg surfaces and antennal scapes. Shape of dorsal surface of propodeum variable in lateral profile but always rounded or arched.

**Measurements.** Worker ($n = 52$): CI 0.92-1.07; EL 0.25-0.35; EW 0.15-0.23; HL 1.12-1.56; HTL 1.41-1.87; HW 1.09-1.63; ML 0.45-0.77; PnL 0.56-0.83; PpL 0.54-0.76; REL 0.20-0.26; SI 0.76-0.99; SL 1.01-1.29.

**Comments.** *Iridomyrmex discors* shows considerable variation in the development of pilosity, especially on the lateral margin of the head; profile of the dorsal propodeum (Figs 5-7); overall size; and colour, especially the infuscation of the legs. This variability has resulted in the establishment of three subspecies and one variety.

---

*Figs 3-9. Iridomyrmex* species, workers: (3) anterior region of head of *I. mayri* group; (4) full face view of *I. discors* (Sturt National Park, N.S.W.); (5) lateral view of mesosoma and petiole of *I. discors* (Sturt National Park, N.S.W.); (6) lateral view of propodeum of *I. discors*, pilosity omitted (Sturt National Park, N.S.W.); (7) lateral view of propodeum of *I. discors*, pilosity omitted (Botany Bay breakwaters, Sydney, N.S.W.); (8) full face view of *I. obscurior* (syntype); (9) lateral view of mesosoma and petiole of *I. obscurior* (syntype).
of *I. discors*. However, during this study variation in the above characters was found to be continuous and the recognition of the earlier proposed forms (except *I. obscurior*, see below) was unjustifiable. Additionally, the original descriptions provide no information helpful in separating or diagnosing these forms. The traits previously used included body colour and iridescence, development of pilosity and head shape, and these supposed differences are now known to be connected by intermediate forms which render them of little use in diagnosing species. For example, head shape was reported to be either narrow or broad. However, quantification of head shape by measuring head width and head length shows continuous variation with the type specimens of the proposed subspecies spanning nearly the complete range of this variation (Fig. 1). The variation in scape length shows a similar pattern, again with type specimens of the earlier taxa showing the extremes of the variation for this character (Fig. 2). Because of this, the names *I. discors aeneogaster* Wheeler, *I. discors occipitalis* Forel and *I. discors occipitalis exilior* Forel (an unavailable infrasubspecific name) are here considered to be junior synonyms of *I. discors*.

The known distribution of *I. discors* shows two distinct, allopatric populations, an eastern one in central and eastern Queensland and eastern New South Wales, and a western one extending from western Queensland, New South Wales and Victoria westward (Fig. 10). *I. discors* is not known to occur in the intervening region even though this area has been relatively well collected. Given that the habitat across this region is fairly uniform and changes only gradually, this disruption in distribution would suggest that two separate forms are present.

A detailed morphological analysis of material from both the eastern and western populations reveals only slight morphological differentiation. The eastern population tends to be slightly darker in overall colour compared to the western population. However, all colour forms can be found in both populations. Additionally, the anterior region of the dorsal propodeal face is flat in the eastern population (Fig. 7), while the majority of specimens from the western population have this region weakly convex (Figs 5, 6), but with a small proportion being flat (similar to Fig. 7). Thus while there is some degree of morphological divergence between these two populations neither possesses unique, diagnostic characters not shared with the other population, and therefore both populations are here considered to belong to a single species.

---

**Fig. 10.** Distribution of *Iridomyrmex* species examined during this study. Closed squares = *I. discors*, closed circles = *I. obscurior*. 
The available biological information suggests that *I. discors* is a general predator/scavenger and occupies a variety of drier habitats, including arid and semi-arid grasslands and shrublands, dry sclerophyll and *Callitris* woodlands. Nests are in soil, often with a low, dispersed layer of loose dirt around the entrance.

**Iridomyrmex obscurior** Forel stat. nov.  
(Figs 1, 2, 8-10)

**Types.** Victoria: 5 worker syntypes from Ballarat (1 worker in ANIC; 4 workers in MHNG).

**Worker diagnosis.** Head narrow (CI less than 0.94) (Fig. 1); scapes long (SI greater than or equal to 1.00) (Fig. 2); propodeal dorsal surface flatter in lateral profile (Fig. 9).

**Worker description.** Pigment colour of head and mesosoma dark yellowish-red and with the pronotum slightly lighter; petiole and gaster dark reddish-black to black; coxae and legs infuscated dark brown. Iridescence absent to weak blue on gaster. Head with numerous erect setae on occipital and lateral margins. Dorsal surfaces of mesosoma, petiole and gaster with numerous elongate erect or suberect hairs; erect hairs present on all leg surfaces and antenna1 scapes. Shape of dorsal surface of propodeum low and flattened medially.

**Measurements.** Worker (n = 6): CI 0.91-0.93; EL 0.25-0.27; EW 0.15-0.16; HL 1.19-1.29; HTL 1.41-1.48; HW 1.10-1.19; ML 0.52-0.57; PnL 0.57-0.67; PpL 0.61-0.66; REL 0.22-0.23; SI 1.00-1.05; SL 1.14-1.19.

**Comments.** *Iridomyrmex obscurior* is currently known from only two collections, the original specimens described by Forel (1902) and a second collection made recently near Canberra, A.C.T. Specimens from both collections are morphologically similar although the type material is noticeably lighter in colour compared to the A.C.T. specimens. This is presumably caused by fading of the original type specimens. *I. obscurior* is morphologically similar to *I. discors* and was originally described as a subspecies of the latter. The two species differ primarily in the scape length relative to head width, and the shape of the head and dorsal surface of the propodeum. In all known specimens the scape is longer for a given head width in *I. obscurior* than in *I. discors* (Fig. 2). Similarly, the dorsal surface of the propodeum in lateral view in *I. obscurior* is arched anteriorly and posteriorly with the central region nearly flat (Fig. 9), while this surface in *I. discors* is always approximately uniformly arched medially (Figs 5-7) although the anterior region can vary from being arched (Fig. 5) to flat (Fig. 7). Finally, head shape differs between these two species, although the difference is less than in the above characters and several individuals of *I. discors* have head length and width very similar to some individuals of *I. obscurior* (Fig. 1). For example, an individual of *I. discors* from Wolri, Cooloola National Park, Queensland, has a HW of 1.21 mm and a HL of 1.28 mm. This is very similar to the type of *I. obscurior*, which has a HW of 1.19 mm and a HL of 1.29 mm. However, other members of this same nest series have head dimensions which are more typical of *I. discors*. These individuals have HWs of 1.28 and 1.29 mm and HLs of 1.29 and 1.36 mm, respectively. The likelihood that this similarity is caused by gene flow is small given that the specimens with similar head shapes are allopatric, and therefore these taxa are maintained as valid, distinct species.

The only biological information available for this species is that the A.C.T. specimens were collected attending lycaenid pupae.
